

Running Hadoop Programs on cslvm Cluster

Overview

This document contains information that is specific to running Hadoop programs on our local cluster.

Local Hadoop Clusters. We plan on installing the Hadoop infrastructure on some of the machines in the MPAC (High-Performance Computing) lab to give us the opportunity to actually run Hadoop jobs on powerful clusters. This requires non-trivial setup.

Because of this, our first introduction to working with Hadoop will take place on a small CSLVM cluster.

CSLVM Hadoop Cluster

We have a Hadoop installation running on `cslvm57`, `cslvm56` and `cslvm55` machines. You currently have access to `cslvm57` and will be running Hadoop from there

To successfully run Hadoop jobs on the cluster, you need to know the following.

Location of Hadoop Binaries. The `hadoop`, `hdfs`, and `yarn` binaries are located in `/usr/bin`.

Our Hadoop installation is version 2.7.

Java Hadoop Package. Core Hadoop library is available in the `hadoop-core-1.2.1.jar` jar file. The file can be downloaded from the course web page:

<http://users.csc.calpoly.edu/~dekhtyar/369-Winter2017/code/hadoop-core-1.2.1.jar>

Note: This file may be out of date. We will provide a new `org.apache.hadoop` implementation once we discover it.

Compiling Hadoop code. To compile a Hadoop job located in file `myJob.java`, place the `hadoop-core-1.2.1.jar` file in the directory where `myJob.java` is located and run the following command from that directory:

```
$ javac -cp hadoop-core-1.2.1.jar myJob.java
```

Note: To stop proliferation of the `hadoop-core-1.2.1.jar` I recommend creating a `~userid/jars` directory, placing the jar file there, and adding the `jars` directory to the classpath.

Making a Jar of your Hadoop Job. Hadoop allows running `.class` files only on local installations. Our Hadoop is installed as a three-node cluster. On such installations, all Hadoop jobs must be packaged as jars.

To create a jar for your Hadoop job, run the following command (after compiling the code):

```
$ jar cvf myJob.jar *.class
```

Alternatively, you can create a simple `manifest.txt` file with the content:

```
Main-Class: myJob
```

and create a jar file using the command:

```
$ jar cvf myJob.jar manifest.txt *.class
```

Removing .class files. In some situations your jar files won't execute correctly unless you remove the `.class` files after creating the jar file.

Running your Hadoop Jobs. Once you created the jar file, you can run it as follows.

```
$ hadoop jar myJob.jar myJob <hadoop job arguments>
```

The last argument of the command *before* `<hadoop job arguments>` is the Java class that contains the `public static int main()` method. If you created your jar file with a `manifest.txt` file as discussed above, you can omit the Java class name:

```
$ hadoop jar myJob.jar <hadoop job arguments>
```

`<hadoop job arguments>` are any of the command-line arguments you need to pass to the `public static int main()` of your program. Often these are the locations of the input files and output directory.

Monitoring your job. Hadoop provides a web service allowing one to monitor the status of Hadoop jobs via a browser. Because `cs1vm55` does not have pinholes set, this is only possible if you are currently on campus, or running a campus VPN client on your machine.

The URL for the Hadoop monitor is

`http://cs1vm55.csc.calpoly.edu:8088/cluster`

Third party Jars. For more complex Hadoop jobs you often may need third-party Jar files to be used with the `Mapper` and/or `Reducer` code. Because the `Mapper` and `Reducer` jobs run in separate JVMs on the cluster, their classpath environments are different than the classpath environment of the `public static int main()`. Fortunately, Hadoop allows us to pass third-party jars to the cluster JVMs using the `-libjars` option.

The full command to run a Hadoop job from `myJob.jar` file that relies on a third-party jar file `foo.jar` and another third party jar file `bar.jar`:

```
$ hadoop jar myJob.jar myJob -libjars foo.jar,bar.jar <hadoop job arguments>
```
