Data Mining: Classification/Supervised Learning

Definitions

Data. Consider a set $A = \{A_1, \ldots, A_n\}$ of attributes, and an additional categorical attribute C, which we call a **class attribute** or **category attribute**.

$dom(C) = \{c_1, \ldots, c_k\}$. We call each value c_i a **class label** or a **category label.**

The **learning dataset** is a relational table D.

Two formats:

1. **Training (data)set**. D has schema $(A_1, \ldots, A_n, C)$, i.e.,

   for each element of the dataset we are given its class label.

2. **Test (data)set**. D has schema $(A_1, \ldots, A_n)$, i.e.,

   the class labels of the records in D are not known.

Classification Problem. Given a (training) dataset D, construct a **classification/prediction function** that correctly predicts the class label for every record in D.

Classification function = **prediction function** = **classification model** = **classifier**.

Supervised learning because training set contains class labels. Thus we can compare (supervise) predictions of our classifier.

Classification Methodology

Naïve Bayes. Estimation of probability that a record belongs to each class.

Neural Netowoks. Graphical models that construct a "separation function" based on the training set data.

Support Vector Machines (SVMs). Linear models for two-class classifiers.

Association Rules. Infer association rules with class label on the right side.

Decision Trees. Build a tree-like classifier. (**key advantage:** human-readable!)

Decision Trees

Decision tree-based classifiers are **simple** and **efficient**.

Decision trees. Let $A = \{A_1, \ldots, A_k\}$ are the dataset attributes and C is a class label. Let $dom(C) = \{c_1, \ldots, c_k\}$. A **decision tree** over A and C is a tree $T = \langle V, E \rangle$ such that,

1. Each **non-leaf** node $v \in V$ is labeled with some $A_i \in A$.
2. Each **leaf** node $v_l \in V$ is labeled with some **class label** $c_i \in dom(C)$.
3. Each edge $E = (v, v')$, where $label(v) = A_i$ is labeled with some value $a \in dom(A_i)$.
4. No attribute $A_i \in A$ can appear more than **once** on each path from root to leaf.

A **decision tree** can be used as a classifier as follows:

- Consider a record $t = (a_1, a_2, \ldots, a_n)$.
- Start at the root node r of the decision tree T. Let $label(r) = A_i$. Find the edge $e = (r, v)$, such that $label(e) = t(A_i) = a_i$, i.e., *follow the outgoing edge from r that is labeled with the value of A_i in t.*
- For node v visited next, continue the same process: follow the outgoing edge labeled with the value of the $label(v)$ attribute found in t.
- When you reach leaf node l, the label $label(l)$ will be the $class(t)$.

C4.5 Algorithm: Induction of Decision Trees

Te **C4.5. Algorithm** for decision tree induction was originally proposed by Quinlan in [1].

Input/Ouput The **C4.5** algorithm for decision tree induction has three parameters:

Name	I/O	Explanation
D	input	the training dataset
A	input	the list of attributes
T	ouput	the constructed decision tree

Algorithm idea. The **C4.5 Algorithm** is a recursive decision tree induction algorithm. The algorithm has the following three main steps:

1. Termination conditions. The algorithm has two termination conditions:
   (a) D contains records with the same class label c. In this case, the algorithm creates a tree that consists of a single node, and assigns to it the class label c.
   (b) $A = \emptyset$: there are no more attributes left to consider. In this case, the algorithms creates a tree that consists of a single node, and assigns to it the label of the plurality records in D.
2. Selection of the splitting attribute. The algorithm chooses the attribute A_i to be used to split the dataset.
3. Tree construction. The algorithm does the following:
   (a) Creates a tree node r labeled A_i.
   (b) Splits the dataset D into $dom(A_i)$ subsets $D_1, \ldots D_{|dom(A_i)|}$, and recursively calls itself for each subset D_j, with the reduced list of attributes $A - \{A_i\}$.
   (c) Creates $|dom(A_i)|$ edges from r to the roots for trees $T_1, \ldots, T_{|dom(A_i)|}$ returned by the recursive calls. Labels each edge with the appropriate value from $dom(A_i)$.
   (d) Returns the constructed tree.

The pseudocode for the **C4. Algorithm** is shown in Figure 1.

Selection of the Splitting Attribute

The **C4.5. Algorithm** relies on an external function to identify the splitting attribute on each step. In this section we discuss how to find splitting attributes.

Information Entropy. Consider a relational dataset D over a list of attributes $A = \{A_1, \ldots, A_n, C\}$, where C is the class attribute of D. Let $dom(C) = \{c_1, \ldots c_k\}$. Let $D_i = \{t \in D | class(D) = c_i\}$. Thus, $D = D_1 \cup D_2 \cup \ldots \cup D_s$.

As $Pr(C = c_i)$ we denote the probability that a randomly chosen record $t \in D$ will have the class label of c_i. We can see that

$$Pr(C = c_i) = \frac{|D_i|}{|D|}.$$

The **entropy** of the dataset D w.r.t. C is defined as follows:

$$entropy(D) = -\sum_{i=1}^{k} Pr(C = c_i) \cdot \log_2(Pr(C = c_i)).$$

Entropy is measured in **bits**.

(**Note:** In this computation, we assume that $0 \cdot \log_2(0) = 0$.)

```
Algorithm C45(D, A, T, threshold);
begin       // Step 1:  check termination conditions
 if for all d ∈ D: class(d) = c_i then
    create leaf node r;
    label(r) := c_i;
    T := r;
 else if A = ∅ then
    c := find_most_frequent_label(D);
    create leaf node r;
    label(r) := c;
 else //Step 2:  select splitting attribute
    A_g := selectSplittingAttribute(A,D, threshold);
    if A_g = NULL then //no attribute is good for a split
      create leaf node r;
      label(r) := find_most_frequent_label(D);
      T := r;
    else // Step 3:  Tree Construction
      create tree node r;
      label(r) := A_g;
      foreach v ∈ dom(A_g) do
        D_v := {t ∈ D|t[A_g] = v};
        if D_v ≠ ∅ then
          C45(D_v, A − {A_g}, T_v);    //recursive call
          append T_v to r with an edge labeled v;
        endif
      endfor
    endif
 endif
end
```

Figure 1: C4.5 algorithm for decision tree induction.

```
function selectSplittingAttribute(A, D,threshold);  //uses information gain
begin
  p0 := enthropy(D);
  for each A_i ∈ A do
    p[A_i] := enthropy_{A_i}(D);
    Gain[A_i] = p0 − p[A_i];   //compute info gain
 endfor
  best := arg(findMax(Gain[]));
  if Gain[best] >threshold  then return best
  else  return NULL;
end
```

```
function selectSplittingAttribute(A, D,threshold);  //uses information gain ratio
begin
  p0 := enthropy(D);
  for each A_i ∈ A do
    p[A_i] := enthropy_{A_i}(D);
    Gain[A_i] := p0 − p[A_i];   //compute info gain
    gainRatio[A_i] := Gain[A_i]/enthropy(A_i);   //compute info gain ratio
 endfor
  best := arg(findMax(gainRatio[]));
  if Gain[best] >threshold  then return best
  else  return NULL;
end
```

Figure 2: selectSplittingAttribute() functions using infomration gain and information gain ratio measures.

Properties of entropy. Entropy of a random variable defined the predictability of the observed results. If certain values are more likely, it is *easier* to predict the outcomes. If all values are equally likely, it is much harder to do so.

The higher the entropy, the more unpredictable are the outcomes.

The entropy of a *homogenous* dataset in which each class label has the same probability of occuring is $\log_2 k$, i.e., the number of bits necessary to represent k.

$$entropy(D) = -\sum_{i=1}^{k} \frac{1}{k} \cdot \log_2 \left(\frac{1}{k}\right) = -\log_2 \left(\frac{1}{k}\right) \cdot \sum_{i=1}^{k} \frac{1}{k} = \log_2 k$$

The enthropy of a dataset where only one class label out of k is present is 0.

$$entropy(D) = -\sum_{i=1}^{k-1} 0 \cdot \log_2 0 - 1 \cdot \log_2 1 = 0.$$

Entropy measures the impurity of data. The higher the *enthropy*, the more *impure* the data is.

Information Gain. Idea: we want to select the attribute that splits the dataset D into **most pure** subsets. We introduce **information gain** measure. Given a dataset D over the list $A = \{A_1, \ldots A_k\}$ of attributes, the *entropy of D after being split using attribute A_i* with domain $dom(A_i) = \{v_1, \ldots, v_s\}$ is defined as:

$$entropy_{A_i}(D) = \sum_{j=1}^{s} \frac{|D_j|}{|D|} \cdot entropy(D_j),$$

where $D_j = \{t \in D | t[A_i] = v_j\}$.

The **information gain** achieved by the split is the difference between the enthropy of D before and after the split:

$$Gain(D, A_j) = entropy(D) - entropy_{A_j}(D).$$

Information Gain Ratio. **Information Gain Ratio** is the normalized version of the information gain measure:

$$gainRatio(D, A_j) = \frac{Gain(D, A_j)}{-\sum_{j=1}^{s} \left(\frac{|D_j|}{|D|} \cdot \log_2 \frac{|D_j|}{|D|}\right)}$$

(essentially, we normalize **information gain** by the "entropy" of the split itself.)

Using Information Gain and Information Gain Ratio to select splitting attributes

Figure 2 shows the two versions of the selectSplittingAttribute() function. The first version uses the **information gain** measure to determine the splitting attribute, while the second version uses the **information gain ratio**.

Both algorithms do the following:

1. Compute the enthropy of the current dataset.
2. Compute the enthropy after splitting the dataset using each of the available attributes.
3. Find the attribute with the best **information gain**/**information gain ratio**.
4. If the **information gain**/**information gain ratio** exceed the threshold, the attribute is returned. Otherwise, `NULL` is returned, as no attribute leads to a significant improvement in the enthropy.

Classifier Evaluation

Accuracy Measures

Notation. Let T be a classifier constructed by **any** supervised learning algorithm given a **training set** D.

Let D' be a **test set**, ***drawn from the same data/distribution as*** D.

Let $t \in D'$. As $T(t)$ we denote the **class label** supplied for t by the classifier T.

As $class(t)$ we denote the **actual** class label of t.

As D_{true} we denote the *set of all test cases for which our classifier provides correct prediction*:

$$D_{true} = \{t \in D' | T(t) = class(t)\}$$

As D_{error} we denote the *set of all test cases for which our classifier provides incorrect prediction*:

$$D_{error} = \{t \in D' | T(t) \neq class(t)\}$$

Accuracy. The **accuracy** of the classifier T is:

$$accuracy(T) = \frac{|D_{true}|}{|D'|}.$$

Error rate. The **error rate** of the classifier T is:

$$errorRate(T) = 1 - accuracy(T) = \frac{|D_{error}|}{|D|}.$$

Accuracy Measures for Binary Classification

Binary Classifiers. Many classifiers are **binary**: i.e., the class variable C has only two values. A classifiaction problem with $dom(C) = \{c_1, \ldots c_k\}$, $k > 2$ can be transformed into k classification problems with class variables $C_1, C_2, \ldots, C_k$, such that, $dom(C_i) = \{0, 1\}$. $C_i = 1$ means $C = c_i$.

Classification Errors. Consider a binary classification problem with the class variable C, $dom(C) = \{0, 1\}$, where $C = 1$ is interpreted as *"record belongs to class C"* and $C = 0$ is interpreted as *"record does not belong to class C.*

Let T be a classifier for C. Let D' be a test dataset. Given $t \in D$, we can observe four possibilities:

1. **True Positive:** $T(t) = class(t) = 1$;
2. **True Negative:** $T(t) = class(t) = 0$;
3. **False Positive:** $T(t) = 1; class(t) = 0$;
4. **False Negative:** $T(t) = 0; class(t) = 1$;

There are **two types of errors of classification**:

1. **Type I error:** a.k.a. **error of commission** a.k.a. **false positive**: classifier incorrectly classifies a tuple as belonging to class C.
2. **Type II error:** a.k.a. **error of omission** a.k.a. **false negative**: classifier incorrectly classifies a tuple as NOT belongingto class C.

Notation. Conisder the following notation:

1. D_{TP} : set of all **true positives** in D'; $TP = |D_{TP}|$;
2. D_{TN} : set of all **true negatives** in D'; $TN = |D_{TN}|$;
3. D_{FP} : set of all **false positives** in D'; $FP = |D_{FP}|$;
4. D_{FN} : set of all **false negatives** in D'; $FN = |D_{FN}|$;

Confusion Matrix. The information about the accuracy of a **binary classifier** is usually arranged in a form of **confusion matrix**:

	Classified Positive	Classified Negative
Actual positive	TP	FN
Actual negative	FP	TN

Precision. **Precision** of the classifier is the percentage of the correctly *positively* classified records in the set of all positively classified records:

$$precision(T) = \frac{TP}{TP + FP}.$$

Precision measures *how accurately the classifier selects positive examples*, it reaches 100% when the classifier *admits no false positives*.

Recall. **Recall** of the classifier is the percentage of all correctly *positively* classified records in the set of all actual positive records:

$$recall(T) = \frac{TP}{TP + FN}.$$

Recall measures *how successful the classifier is in correctly identifying all positive records.* It reaches 100% when the classifier *admits no false negatives.*

Note: **Precision** and **recall** make sense **only** when combined together.

It is easy to build a classifier with 100% precision: *T(t) = 0* for all $t \in D'$ guarantees that. **But this classifier will have recall of 0**. It is easy to build a classifier with 100% recall: *T(t) = 1* for all $t \in D'$ guarantees that. **But this classifier will have small precision.**

PF. The **PF** measure is defined as:

$$PF(T) = \frac{FP}{FP + TN}.$$

PF measures the *misclassification rate*: the percentage of records **not** in class C that was **incorrectly classified**.

F-measure. The **F-measure** is the harmonic mean of precision and recall:

$$F(T) = \frac{2}{\frac{1}{precision(T)} + \frac{1}{recall(T)}} = \frac{2 \cdot precision(T) \cdot recall(T)}{precicion(T) + recall(T)}.$$

F-measure combines precision and recall into a single number by balancing them against each other.

In some situations, one of the two measures (precision or recall) is more important than the other. **F-measure** can be skewed to favor each. The F_2**-measure** below assumes recall is twice as valuable as precision. The $F_{0.5}$**-measure** below assumes precision is twice as valuable as recall.

$$F_2(T) = \frac{5 \cdot precision(T) \cdot recall(T)}{4 * precision(T) + recall(T)}.$$

$$F_{0.5}(T) = \frac{1.25 \cdot precision(T) \cdot recall(T)}{0.25 * precision(T) + recall(T)}.$$

The formula for F_β, where β represents the relative importance of recall over precision is:

$$F_\beta(T) = \frac{(1 + \beta^2) \cdot precision(T) \cdot recall(T)}{\beta^2 * precision(T) + recall(T)}.$$

Evaluation Techniques

In a typical situation, you are given a **training set** D, and are asked to produce a classifier for it.

If all records from D are used to create a classifier, there will be no way to INDEPENDENTLY test its accuracy.

Holdout set. Divide D into two sets: $D = D_{train} \cup D_{test}$; $D_{train} \cap D_{test} = \emptyset$.

D_{test} is called the **holdout set.**

Create a classifier T using D_{train} as the training set. **Test** T using D_{test}.

Holodout set selection:

- **Random sampling.** Select a fraction x. Randomly sample $x\%$ of records from D, put them in D_{test}.

  Commonly, you use around 90% of D as the training set, reserving the remaining 10% for the holdout set.

- **Time slices.** If D consists of "old" data and "new" data, then, the training set can include all of the "old" data, while the holdout set can include the "new" data. (e.g., in situations where new records appear every day).

Multiple random sampling. This technique is used when D is small.

- Select some number M of repetitions.
- Perform M random samplings of a **holdout set** from D. Run classifier construction on the remaining set D_{train}. Compute the accuracy of the classifier for the current sample.
- Compute the final accuracy as the mean accuracy over all samples.

Multiple random sampling allows us to avoid *flukes* (or, at least, to downgrade their effects).

Cross-Validation. This is a variant of **multiple random sampling** that uses only one random assignment of records, but performs multiple classifications.

- Select n – the number of *slices* of data in D.
- Using *random sampling* split D into n *slices* of equal (or almost equal) size.
- Peform n classification procedures. On step i, use slice D_i as the **holdout set**, while using all other $n - 1$ slices as the **training set**.

Note: Standard cross-validations used in practice are **10-fold**, **5-fold** and **leave-one-out** cross-validations.
