Machine Learning: Feed-Forward Neural Nets

Overview

Perceptrons. A perceptron is a linear classifier of the form $y = sign(\sigma_{i=1}^{d} w_i x_i + b)$ where the weights $w = (w_1, \ldots, w_d)$ are trained using *stochastic gradient descent*. A perceptron is guaranteed to converge to *some* hyperplane separating two classes *if the two classes are linearly separable* (i.e., if there exists at least one hyperplane such that all points from Class 1 are on one side of it and all points from Class 2 are on the other side).

Support Vector Machines. A Support Vector Machine is a perceptron enhanced with the ability to classify non-linearly separable datasets.

General Support Vector Machines enhance perceptrons in two ways:

- Support Vector Machines optimize the hinge-loss (or quadratic hinge-loss) of the dataset w.r.t. a given separating plane. This allows for classifying non-linearly separable data sets.
- Support Vector Machines can use something called *the kernel trick*. Specifically, SVMs can generalize the $\sum_{i=1}^{d} w_i x_i = \bar{w} \cdot \bar{x}$ inner product of the vector of weights and the data to be *any*, possbily non-linear, function that exhibits properties of the inner product. Because of the *kernel trick*, SVMs that use non-linear kernels instead of dot-products can build non-linear separating curves.

Gadient Descent. Most of the classification and prediction problems we have seen so far turned out to be *multivariate optimization problems*. Gradient Descent is a well-known iterative (approximation) method for searching for (local) optima of multivariate functions.

Given a function $f(x_1, \ldots, x_d)$ that needs to be *minimized*, gradient descent starts with a point $\bar{x_0} = (x_{01}, \ldots, x_{0d})$, and a learning rate $\nu > 0$, and proceeds as follows:

$$\bar{x_{i+1}} = \bar{x_i} - \nu \nabla f(\bar{x_i}),$$

or

$$x_{x+1,j} = x_{i,j} - \nu \frac{\partial f}{\partial x_j}(\bar{x_i})$$

for each $j = 1, \ldots, d$.

Stochastic Gradient Descent. The stochastic gradient descent is a variation of the gradient descent method, where the gradient is computed after selecting a small subsample of data points from the dataset, rather than from going through the entire dataset in a single pass. Stochastic Gradient Descent is not as fast at convergence, but it is faster in processing as it samples a small number of points for each step of the gradient descent process.

Non-linear transition functions. The key idea behind the perceptron is that the class of a data point $\bar{x}$ can be computed as a linear combination $w \cdot \bar{x}$, against which a learned threshold b can be applied: if $w \cdot \bar{x} > b$, $\bar{x}$ belongs to one class, otherwise - to the other.

The disadvantage of a linear transition function that is thresholded at some value b is two-fold:

- The function $f(x) = 1$ if $x > b$ and $f(x) = -1$ if $x < b$ is not differentiable at $x = b$, which means that one cannot use gradient descent methods to approximate it.
- The linear function $f(\bar{x}) = w \cdot \bar{x})$ by itself is slow-growing.

We would like to replace the threshold function with a *differentiable function* which *transitions* from -1 to +1 value *very fast*.

We have seen two such functions already, when discussing *logistic regression*:

$$\sigma(x) = \frac{1}{1 + e^x}$$

and

$$tanh(x) = \frac{sinh(x)}{cosh(x)} = \frac{e^x - e^{-x}}{e^x + e^{-x}} = \frac{1 - e^{-2x}}{1 + e^{-2x}}$$

Neuron. A neuron is essentially a perceptron with a non-linear *transition function*. Where a perceptron supplied with a vector $w = (w_1, \ldots, w_d)$ of weights and a threshold θ produces the following computations:

$$y = f(\bar{x}) = \sum_{i=1}^{d} w_i x_i = w \cdot \bar{x}$$

followed by

$$output(\bar{x}) = \begin{cases} +1 & \text{if } y > \theta; \\ -1 & \text{if } y < \theta; \end{cases},$$

The neuron, replaces the second step with the computation

$$output(\bar{x}) = h(y),$$

where h is a predefined transition function. For example, a neuron using the sigmoid function $sigma(x)$ has the following output:

$$output(\bar{x}) = \frac{1}{1+e^{y}} = \frac{1}{1+e^{w\cdot\bar{x}-\theta}}$$

Feed-Forward Neural Networks

The idea behind Support Vector Machines is to make a single perceptron into a more complex decision procedure.

The idea behind Feed-forward Neural Networks is to use many simple neurons together and to *layer* them.

Feed-Forward Neural Network. A feed-forward neural network consists of a set of input variables $X_1, \ldots, X_d$, a set of hidden layers $L_1, \ldots, L_M$, where each layer l consists of a set $\{N_{l1}, \ldots, N_{l,m_l}\}$ of *nodes* or *neurons*, and an output layer $Y_1, \ldots, Y_K$ of neurons. The following applies:

- Each input variable X_i is connected to all nodes from the first hidden layer: i.e., the neural net contains the edges of the form (X_i, N_{1j}) for all $i = 1, \ldots, d$ and $j = 1, \ldots m_1$.
- Each for $j = 1, \ldots M-1$ each neuron in hidden layer L_j is connected to each neuron in hidden layer L_{j+1}: i.e., the neural net contains the edges of the form $(N_{j,i}, N_{j+1,k})$ for $i = 1, \ldots m_j$, $j = 1, \ldots m_{j+1}$.
- Each neuron in the hidden layer L_M is connected to each output Y_k: i.e., the neural net contains the edges of the form $(X_{M,i}, Y_k)$ for $i = 1, \ldots, m_M$, $k = 1, \ldots, K$.
- With each neuron $N_{j,i}$ and output neuron Y_j we associate a linear transformation function:

  $$a_{ji} = \mathbf{w_{ji}} \cdot \bar{\mathbf{x}} + \mathbf{b_{ji}},$$

  where

  $$w_{ji} = (w_{ji,1}, \ldots, w_{ji,k_j})$$

  and b_{ji} are the weights and the bias associated with the neuron N_{ji} (the ith neuron in hidden layer j), and k_j is defined as follows:

  $$k_j = \begin{cases} d & \text{if } j = 1 \\ m_{j-1} & \text{if } j > 1 \end{cases},$$

  Here, we implicitly consider the output neurons to form the $M+1$st layer of the network.

- With each neuron $N_{j,i}$ and output neuron Y_j we associate an activation function $h_{j,i}$:

$$z_{j,i} = h_{j,i}(a_{ji}) = h_{ji}(\mathbf{w_{ji}} \cdot \bar{\mathbf{x}} + \mathbf{b_{ji}}).$$

  Here, h_{ji} are **non-linear** sigmoid functions (e.g., $\sigma(x)$ or $tanh(x)$).

  Usually, all neurons use the same activation function, although in some cases, the activation function for output layer may be different than those of the hidden layers.

Notation. We use h_j to denote the vector $(h_{j1}, \ldots, h_{jk_j})$ and a_j to denote the vector $(a_{j1}, \ldots, a_{jk_j})$.

Based on this description, a feed-forward neural network represents a **non-linear transformation** of d inputs $X_1, \ldots, X_d$ into K outputs $Y_1, \ldots Y_K$ produced as follows:

$$\bar{y} = h_{M+1}(a_{M+1}),$$

or

$$y_k = h_{M+1,k}(a_{M+1,k}) = h_{M+1,k}\left(\sum_{i=1}^{k_M} \mathbf{w_{Mi}} \cdot h(a_M) + b_{Mi}\right).$$

Example. Two-layer feed-forward network. Consider a standard example of a neural network with an input layer $X_1, \ldots, X_d$, a **single** hidden layer $N_1, \ldots, N_M$ and an output layer $Y_1, \ldots, Y_K$ and $\sigma(x) = \frac{1}{1+e^x}$ as the activation function for each neuron. Let us denote as $\mathbf{w}_1, \ldots \mathbf{w}_M$ and $b_1, \ldots b_M$ the weights and the biases for neurons in the hidden layer, and as $\mathbf{v_1}, \ldots, \mathbf{v}_K$ and $c_1, \ldots, c_K$ the weights and the biases of the neurons in the output layer.

Then, each output y_k can be computed as follows:

$$y_k = \sigma\left(\sum_{i=1}^{M} v_{ki} \cdot \sigma\left(\sum_{j=1}^{d} w_{ij}x_j + b_i\right) + c_k\right)$$

Training Feed-Forward Network

To train a neural network we need a dataset $X = \{\bar{x_1}, \ldots, \bar{x_n}\}$, and a set $T = \{t_1, \ldots, t_n\}$ where $t_i = class(\bar{x_i})$. In a more general case, we consider the output T to be a set of vectors $T = \{\bar{t_1}, \ldots, \bar{t_n}\}$, where t_{ij} is the output of the jth classifier (represented by the neural network output element Y_j) on input $\bar{x_i}$.

Given a neural network Q with k outputs $Y = \{Y_1, \ldots, Y_k\}$, let vector $\bar{y_i} = (y_{i1}, \ldots, y_{ik})$ denote the outputs produced by Q on input vector $\bar{x_i}$.

We want to compare the vectors $\bar{t_i}$ and $\bar{y_i}$, and we want these two vectors to be as close to each other as possible for all $i = 1, \ldots, n$.

Our standard metric for this is the SSE: sum squared errors. For a given output Y_j:

$$E_j(\bar{x_i}) = (t_{ij} - y_{ij})^2$$

The error is additive, so

$$E(\bar{x_i}) = \sum_{j=1}^{k} E_j(\bar{x_i}) = \sum_{i=1}^{k} (t_{ij} - y_{ij})^2$$

Finally, the full error of the dataset is

$$E_X = \sum_{i=1}^{n} E(\bar{x}) = \sum_{i=1}^{n} \sum_{j=1}^{k} E_j(\bar{x_i}) = \sum_{i=1}^{n} \sum_{j=1}^{k} (t_{ij} - y_{ij})^2$$

Let $\mathbf{W}$ represent the vector of **all** weights for all neurons in the network Q. As the network is trained, the above error computation is parameterized by $\mathbf{W}$:

$$E_X(\mathbf{W}) = \sum_{i=1}^{n} E(\bar{x}) = \sum_{i=1}^{n} \sum_{j=1}^{k} E_j(\bar{x_i}) = \sum_{i=1}^{n} \sum_{j=1}^{k} (t_{ij} - y_{ij})^2$$

Because our error is additive, we can apply both the *gradient descent* and *stochastic gradient descent* to approximate the optimal (or a sufficiently good) value.

How do we apply this to the shape of our function(s) computing values y_{ik}.

Backpropagation Algorithm

The basic outline of our training process is as follows.

1. **Initialization.** Select a starting set of parameters $\mathbf{w}_{lj}$ for each neuron in layers $L_1, \ldots, L_M$ and Y of the neural net.
2. **Step.** Each learning step is done in two stages.
   - **Stage 1: Forward propagation.** On step s Select a *batch* of input points $X_s \subseteq X$. For each $\bar{x} \in X_s$ compute the outputs of each layer using current vectors of weights $\mathbf{w}_{lj}$.
   - **Stage 2: Back propagation.** Starting with the output layer, apply gradient descent on the given batch X_s of points to change the weights of the neurons in each layer.
3. **Stoppage condition.** Stop when the error is small, or when the error stops changing significantly from round to round.

The key observation here is that the actual *gradient descent* does not have to be computed on the entirety of the functions used for computing y_ks: rather, it can be done by unwrapping the $h(\mathbf{w} \cdot \bar{x})$ components representing computations on individual neurons, one-by-one, through, what we can call, *local information exchange*.

Here is the mechanics of it for a single layer.

Consider a single output neuron Y. For a data point $\bar{x}$, let t be $class(\bar{x})$ and y be the output of the network's Y neuron on $\bar{x}$.

Let the prior hidden layer L consist of neurons $N_1, \ldots, N_m$, and let $w = (w_0, \ldots, w_m)$ be weights associated with Y, with w_0 representing the bias of node Y. Let $\bar{z} = 1, z_1, \ldots, z_m$ be the outputs of neurons $N_1, \ldots N_m$ on input $\bar{x}$ (with 1 corresponding to the ever-present bias).

The output y is then produced as follows:

$$y = h\left(\sum_{j=0}^{m} w_j z_j\right),$$

where $h()$ is a differentiable non-linear sigmoid activation function.

Our error function is then

$$E(\bar{z}, \mathbf{w}) = \frac{1}{2}(t-y)^2 = \frac{1}{2}\left(t - h\left(\sum_{j=0}^{m} w_j z_j\right)\right)^2$$

(note: we added the $\frac{1}{2}$ fraction to make differentiating easier).

Let us differentiate $E(\bar{z}, \mathbf{w})$ on $\mathbf{w}$ now.

$$\nabla E = (y-t)\cdot\nabla y = (y-t)\cdot\nabla\left(h\left(\sum_{j=0}^{m} w_j z_j\right)\right) =$$

$$= (y-t)\cdot h'\left(\sum_{j=0}^{m} w_j z_j\right)\nabla\left(\sum_{j=0}^{m} w_j z_j\right)$$

To compute partial differentials, let us denote outputs of neurons prior to activation:

$$a = \mathbf{w}\cdot\bar{z},$$

where $\bar{z}$ is a vector of inputs from the previous layer (or is $\bar{x}$ for the first hidden layer). This lets us represent the gradient as:

$$\nabla E = (t-y)h'(a)\nabla(a) = (t-y)h'(a).$$

We now need to evaluate the partial derivatives $\frac{\partial E}{\partial w_j}$. Using the chain rule, we can write:

$$\frac{\partial E}{\partial w_j} = \frac{\partial E}{\partial a}\cdot\frac{\partial a_j}{\partial w_j}$$

Let us denote $\frac{\partial E}{\partial a}$ as δ:

$$\delta = \frac{\partial E}{\partial a}.$$

We refer to δ as the *error* of the neuron.

$$\frac{\partial a}{\partial w_j} = \frac{\partial}{\partial w_j}\left(w_1 z_1 + w_2 z_2 + \ldots + w_j z_j + \ldots + w_m z_m\right) = z_j$$

In the output layer:

$$\delta = y - t$$

In other layers:

$$\delta = \frac{\partial E}{\partial a} = (t - y) h'(a)$$
