ABSTRACT

This paper presents Korat, a novel framework for automated testing of Java programs. Given a formal specification for a method, Korat uses the method precondition to automatically generate all nonisomorphic test cases bounded by a given size. Korat then executes the method on each of these test cases, and uses the method postcondition as a test oracle to check the correctness of each output.

To generate test cases for a method, Korat constructs a Java predicate (i.e., a method that returns a boolean) from the method's precondition. The heart of Korat is a technique for automatic test case generation: given a predicate and a bound on the size of its inputs, Korat generates all nonisomorphic inputs for which the predicate returns true. Korat exhaustively explores the input space of the predicate but does so efficiently by monitoring the predicate's executions and pruning large portions of the search space.

This paper illustrates the use of Korat for testing several data structures, including some from the Java Collections Framework. The experimental results show that it is feasible to generate test cases from Java predicates, even when the search space for inputs is very large. This paper also compares Korat with a testing framework based on declarative specifications. Contrary to our initial expectation, the experiments show that Korat generates test cases much faster than the declarative framework.

1. INTRODUCTION

Manual software testing, in general, and test data generation, in particular, are labor-intensive processes. Automated testing can significantly reduce the cost of software development and maintenance [3]. This paper presents Korat, a novel framework for automated testing of Java programs. Korat uses specification-based testing [4,12,14,26,29]. Given a formal specification for a method, Korat uses the method precondition to automatically generate all nonisomorphic test cases bounded by a given size. Korat then executes the method on each of the test cases, and uses the method postcondition as a test oracle to check the correctness of each output.

To generate test cases for a method, Korat constructs a Java predicate (i.e., a method that returns a boolean) from the method's precondition. One of the key contributions of Korat is a technique for automatic test case generation: given a predicate, and a bound on the size of its inputs, Korat generates all nonisomorphic inputs for which the predicate returns `true`. Korat exhaustively explores the input space of the predicate but does so efficiently by monitoring the predicate's executions and pruning large portions of the search space. Korat also uses an optimization to generate only nonisomorphic test cases. This optimization reduces the search time without compromising the exhaustive nature of the search.

Korat uses backtracking to systematically explore the input space of the predicate. Korat generates *candidate* inputs and checks their validity by invoking the predicate on them. Korat monitors accesses that the predicate makes to all the fields of the candidate input. If the predicate returns without reading some fields of the candidate, then the validity of the candidate must be independent of the values of those fields—Korat uses this observation to prune the search.

Korat lets programmers write specifications in any language as long as the specifications can be automatically translated into Java predicates (i.e., methods that return booleans). The current Korat implementation uses the Java Modeling Language (JML) [20] for specifications. Programmers can use JML to write method preconditions and postconditions, as well as class invariants. JML uses Java syntax and semantics for expressions, and contains some extensions such as quantifiers. A large subset of JML can be automatically translated into Java predicates. Programmers can thus use Korat without having to learn a specification language much different than Java. Moreover, since JML specifications can call Java methods, programmers can use the full expressiveness of the Java language to write specifications.

To illustrate the use of Korat, consider a method that removes the minimum element from a balanced binary tree. The precondition for this method requires the input to satisfy its class invariant: the input must be a binary tree and the tree must be balanced. Korat uses this precondition as the predicate for generating all nonisomorphic balanced binary trees bounded by a given size. Good programming practice [22] suggests that implementations of abstract data types provide predicates that test class invariants (known as the `repOk` or `checkRep` methods)—Korat then generates test cases almost for free. Korat invokes the method on each of the generated trees and checks the postcondition in each case. If a method postcondition is not specified, Korat can still be used to test partial correctness of the method. In the binary tree example, Korat can be used to check the class invariant at the end of the remove method, to verify that the input tree remains a balanced binary tree after removing the minimum element from it.

We have used Korat to test several data structures, including some from the Java Collections Framework. The experimental results show that it is feasible to generate test cases from Java predicates, even when the search space for inputs is very large. In particular, our experiments indicate that it is practical to generate inputs to achieve complete code coverage, even for intricate methods that

```
import java.util.*;
class BinaryTree {
    private Node root; // root node
    private int size;  // number of nodes in the tree
    static class Node {
        private Node left;  // left child
        private Node right; // right child

    }
    public  boolean repOk() {
        // checks that empty tree has size zero
        if (root == null) return size == 0;
        Set visited = new HashSet();
        visited.add(root);
        LinkedList();
        workList.add(root);
        while (!workList.isEmpty()) {
            Node current = (Node)workList.removeFirst();
            if (current.left != null) {
                // checks that tree has no cycle
                if (!visited.add(current.left))
                    return false;
                workList.add(current.left);
            }
            if (current.right != null) {
                // checks that tree has no cycle
                if (!visited.add(current.right))
                    return false;
                workList.add(current.right);
            }
        }
        // checks that size is consistent
        if (visited.size() != size) return false;
        return true;
    }

}
```

Figure 1: `BinaryTree` example

manipulate complex data structures. This paper also compares Korat with the Alloy Analyzer [15], which can be used to generate test cases from declarative predicates. Contrary to our initial expectation, the experiments show that Korat generates test cases much faster than the Alloy Analyzer.

The rest of this paper is organized as follows. Section 2 illustrates the use of Korat on two examples. Section 3 presents the algorithm that Korat uses to explore the search space. Section 4 describes how Korat checks method correctness. Section 5 presents the experimental results. Section 6 reviews related work, and Section 7 concludes.

2. EXAMPLES

This section presents two examples to illustrate how programmers can use Korat to test their programs. These examples, a binary tree data structure and a heap[1] data structure, illustrate methods that manipulate linked data structures and array-based data structures, respectively.

2.1 Binary tree

This section illustrates the generation and testing of linked data structures using simple binary trees. The Java code in Figure 1 declares a binary tree and defines its `repOk` method. The `repOk` method is a Java predicate that checks the representation invariant (or class invariant) of the corresponding data structure [22]. In this case, the `repOk` method checks if the input is a valid `BinaryTree`.

Each object of the class `BinaryTree` represents a tree. The `size` field contains the number of nodes in the tree. Objects of the inner class `Node` represent nodes of the trees. The method `repOk` first checks if the tree is empty. If not, `repOk` traverses all nodes reachable from `root`, keeping track of the visited nodes to detect cycles. (The method `add` from `java.util.Set` returns `false` if the argument already exists in the set.)

[1]The term "heap" refers to the data structure (priority queues) and not to the garbage-collected memory.

```
public static Finitization finBinaryTree(int NUM_Node) {
  Finitization f = new Finitization(BinaryTree.class);
  ObjSet nodes = f.createObjects("Node", NUM_Node);
                                // #Node = NUM_Node
  nodes.add(null);
  f.set("root", nodes);       // root in null + Node
  f.set("size", NUM_Node);    // size = NUM_Node
  f.set("Node.left", nodes);  // Node.left in null + Node
  f.set("Node.right", nodes); // Node.right in null+ Node
  return f;
}
```

Figure 2: Finitization description for the `BinaryTree` example

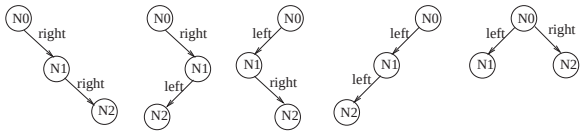

Figure 3: Trees generated for `finBinaryTree(3)`

To generate trees that have a given number of nodes, the Korat search algorithm uses the *finitization* description shown in Figure 2. The statements in the finitization description specify bounds on the number of objects to be used to construct instances of the data structure, as well as bounds on the possible values stored in the fields of those objects. Most of the finitization description shown in the figure is automatically generated from the type declarations in the Java code. In Figure 2, the parameter `NUM_Node` specifies the bound on number of nodes in the tree. Each reference field in the tree is either `null` or points to one of the `Node` objects. Note that the identity of these objects is irrelevant—two trees are *isomorphic* if they have the same branching structure, irrespective of the actual nodes in the trees.

Korat automatically generates all nonisomorphic trees with a given number of nodes. For example, for `finBinaryTree(3)`, Korat generates the five trees shown in Figure 3. As another example, for `finBinaryTree(7)`, Korat generates 429 trees in less than one second.

We now illustrate how programmers can use Korat to check correctness of methods. The JML annotations in Figure 4 specify partial correctness for the example `remove` method that removes from a `BinaryTree` a node that is in the tree. The `normal_behavior` annotation specifies that if the precondition (`requires` conjoined with `invariant`) is satisfied at the beginning of the method, then the postcondition (`ensures` conjoined with `invariant`) is satisfied at the end of the method and the method returns without throwing an exception. The helper method `has` checks that the tree contains the given node. Korat uses the JML tool-set to translate annotations into runtime Java assertions.

To test a method, Korat first generates test inputs. For `remove`, each input is a pair of a tree and a node. The precondition defines valid inputs for the method: the tree must be valid and the node must be in the tree. Given a finitization for inputs (which can be written

```
//@ public invariant repOk(); // class invariant
                              //   for BinaryTree
/*@ public normal_behavior    // specification for remove
  @     requires has(n);      //     precondition
  @     ensures !has(n);      //     postcondition
  @*/
public void remove(Node n) {
    // ... method body
}
```

Figure 4: Partial specification for `BinaryTree.remove`

```
public class HeapArray {
    private int size; // number of elements in the heap
    private Comparable[] array; // heap elements
    public boolean repOk() {
        // checks that array is non-null
        if (array == null) return false;
        // checks that size is within array bounds
        if (size < 0 || size > array.length)
            return false;
        for (int i = 0; i < size; i++) {
            // checks that elements are non-null
            if (array[i] == null) return false;
            // checks that array is heapified
            if (i > 0 &&
                array[i].compareTo(array[(i-1)/2]) > 0)
                return false;
        }
        // checks that non-heap elements are null
        for (int i = size; i < array.length; i++)
            if (array[i] != null) return false;
        return true;
    }
}
```

Figure 5: `HeapArray` example

reusing the finitization description for trees presented in Figure 2), Korat generates all nonisomorphic inputs. For `remove`, the number of input pairs is the product of the number of trees and the number of nodes in the trees. After generating the inputs, Korat invokes the method (with runtime assertions for postconditions) on each input and reports a counterexample if the method fails to satisfy the correctness criteria.

2.2 Heap array

This section illustrates the generation and checking of array-based data structures, using the heap data structure [7]. The (binary) *heap* data structure can be viewed as a complete binary tree—the tree is completely filled on all levels except possibly the lowest, which is filled from the left up to some point. Heaps also satisfy the *heap property*—for every node n other than the root, the value of n's parent is greater than or equal to the value of n. The Java code in Figure 5 declares an array-based heap and defines the corresponding `repOk` method. The `repOk` method checks if the input is a valid `HeapArray`.

The elements of the heap are stored in `array`. The elements implement the interface `Comparable`, providing the method `compareTo` for comparisons. The method `repOk` first checks for the special case when `array` is `null`. If not, `repOk` checks that the `size` of the heap is within the bounds of the `array`. Then, `repOk` checks that the array elements that belong to the heap are not `null` and that they satisfy the heap property. Finally, `repOk` checks that the array elements that do not belong to the heap are `null`.

To generate heaps, the Korat search algorithm uses the finitization description shown in Figure 6. We again emphasize that most of the finitization description shown in the figure is automatically generated from the type declarations in the Java code.

```
public static Finitization finHeapArray(int MAX_size,
                                        int MAX_length,
                                        int MAX_elem) {
    Finitization f = new Finitization(HeapArray.class);
    // size in [0..MAX_size]
    f.set("size", new IntSet(0, MAX_size));
    f.set("array",
          // array.length in [0..MAX_length]
          new IntSet(0, MAX_length),
          // array[] in null + Integer([0..MAX_elem])
          new IntegerSet(0, MAX_elem).add(null));
    return f;
}
```

Figure 6: Finitization description for the `HeapArray` example

```
size = 0, array = []
size = 0, array = [null]
size = 1, array = [Integer(0)]
size = 1, array = [Integer(1)]
```

Figure 7: Heaps generated for `finHeapArray(1,1,1)`

In Figure 6, the parameters `MAX_size`, `MAX_length`, and `MAX_elem` bound the size of the heap, the length of the array, and the elements of the array, respectively. The elements of the array can either be `null` or contain `Integer` objects where the integers can range from 0 to `MAX_elem`.

Given values for the finitization parameters, Korat automatically generates all heaps. For example, for `finHeapArray(1,1,1)`, Korat generates the four heaps shown in Figure 7. As another example, in less than one second, for `finHeapArray(5,5,5)`, Korat generates 1919 heaps.

Note that Korat requires only the `repOk` method and finitization to generate all heaps. Writing a dedicated heap generator is much more involved than writing `repOk`. Note also that Korat allows `repOk` to use the full Java language.

We now illustrate how programmers can use Korat to check partial correctness of the `extractMax` method that removes and returns the largest element from a `HeapArray`. The JML annotations in Figure 8 specify partial correctness for the `extractMax` method. The `normal_behavior` specifies that if the input heap is valid and non-empty, then the method returns the largest element in the original heap and the resulting heap after execution of the method is valid. The JML keywords `\result` and `\old` denote, respectively, the object returned by the method and the expressions that should be evaluated in the pre-state. JML annotations can also express exceptional behavior of methods. The `exceptional_behavior` specifies that if the input heap is empty, the method throws an `IllegalArgumentException`.

To check the method `extractMax`, Korat first uses a finitization to generate all nonisomorphic heaps that satisfy either the `normal_behavior` precondition or the `exceptional_behavior` precondition. Next, Korat invokes the method (with runtime assertions for postconditions) on each input and reports a counterexample if any invocation fails to satisfy the correctness criteria.

3. TEST CASE GENERATION

The heart of Korat is a technique for test case generation: given a Java predicate and a finitization for its input, Korat automatically generates all nonisomorphic inputs for which the predicate returns `true`. Figure 9 gives an overview of the Korat search algorithm.

```
//@ public invariant repOk();
/*@ public normal_behavior
  @     requires size > 0;
  @     ensures \result == \old(array[0]);
  @ also public exceptional_behavior
  @     requires size == 0;
  @     signals (IllegalArgumentException e) true;
  @*/
public Comparable extractMax() {
    // ... method body
}
```

Figure 8: Partial specification for `HeapArray.extractMax`

```
void koratSearch(Predicate p, Finitization f) {
    intialize(f);
    while (hasNextCandidate()) {
        Object candidate = nextCandidate();
        try {
            if (p.invoke(candidate))
                output(candidate);
        } catch (Exception e) {}
        backtrack();
    }
}
```

Figure 9: Pseudo-code of the Korat search algorithm

Korat uses backtracking to exhaustively explore the *state space* of predicate inputs. Korat generates *candidate* inputs and checks their validity by invoking the predicate on them. Korat monitors accesses that the predicate makes to all the fields of the candidate input. To monitor the accesses, Korat instruments the predicate and all the methods that the predicate transitively invokes. If the predicate returns without reading some fields of the candidate, the validity of the candidate must be independent of the values of those fields—Korat uses this observation to prune the search. Korat also uses an optimization that generates only nonisomorphic test cases.

This section first illustrates how Korat generates valid inputs for predicate methods that take only the implicit `this` argument. Section 3.6 shows how Korat generates valid inputs for Java predicates that take multiple arguments.

3.1 Finitization

To generate a finite state space of a predicate's inputs, the search algorithm needs a *finitization*, i.e., a set of bounds that limits the size of the inputs. Since the inputs can consist of objects from several classes, the finitization specifies the number of objects for each of those classes. A set of objects from one class is called a *class domain*. The finitization also specifies for each field of those objects a *field domain*, i.e., a set of values that the field can take.

In the spirit of using the implementation language (which programmers are familiar with) for specification and testing, Korat provides a `Finitization` class that allows finitizations to be written in Java.[2] Korat automatically generates a finitization *skeleton* from the type declarations in the Java code. For the `repOk` method of the `BinaryTree` example presented in Figure 1, Korat automatically generates the skeleton shown in Figure 10.

In Figure 10, the `createObjects` method specifies that the input contains at most `NUM_Node` objects from the `Node`. The `set` method specifies the field domain for each field. In the skeleton, the fields `root`, `left`, and `right` are specified to contain either `null`

[2]The initial version of Korat provided a special-purpose language for more compact descriptions of finitizations, sketched in the comments in the examples in Figures 2 and 6.

```
public static Finitization finBinaryTree(int NUM_Node,
                                         int MIN_size,
                                         int MAX_size) {
  Finitization f = new Finitization(BinaryTree.class);
  ObjSet nodes = f.createObjects("Node", NUM_Node);
  nodes.add(null);
  f.set("root", nodes);
  f.set("size", new IntSet(MIN_size, MAX_size));
  f.set("Node.left", nodes);
  f.set("Node.right", nodes);
  return f;
}
```

Figure 10: Generated finitization description for `BinaryTree`

or a `Node` object. The `size` field is specified to range between `MIN_size` and `MAX_size` using the utility class `IntSet`. The Korat package provides several additional classes for easy construction of class domains and field domains.

Once Korat generates a finitization skeleton, programmers can further specialize or generalize it. For example, the skeleton shown in Figure 10 can be specialized by setting `MIN_size` to 0 and `MAX_size` to `NUM_Node`. We presented another specialized finitization in Figure 2. Note that programmers can use the full expressive power of the Java language for writing finitization descriptions.

3.2 State space

We continue with the `BinaryTree` example to illustrate how Korat constructs the state space for the input to `repOk` using the finitization presented in Figure 2. Consider the case when Korat is invoked for `finBinaryTree(3)`, i.e., `NUM_Node = 3`. Korat first allocates the specified objects, one `BinaryTree` object and three `Node` objects. The three `Node` objects form the `Node` class domain. Korat then assigns a field domain and a unique identifier to each field of these objects. The identifier is the index into the *candidate vector*. In this example, the vector has eight elements; there are total of eight fields: the single `BinaryTree` object has two fields, `root` and `size`, and each of the three `Node` objects also has two fields, `left` and `right`.

For this example, a *candidate* `BinaryTree` input is a sample valuation of those eight fields. The state space of inputs consists of all possible assignments to those fields, where each field gets a value from its corresponding domain. Since the domain for fields `root`, `left`, and `right` has four elements (`null` and three `Nodes` from the `Node` class domain), the state space has $4*1*(4*4)^3 = 2^{14}$ potential candidates. For `NUM_Node`$= n$, the state space has $(n+1)^{3n}$ potential candidates. Figure 11 shows an example candidate that is a valid binary tree on three nodes. Not all valuations are valid binary trees. Figure 12 shows an example candidate that is not a tree; `repOk` returns `false` for this input.

3.3 Search

To systematically explore the state space, Korat orders all the elements in every field domain and every class domain. Each candidate input is then a vector of indices into the corresponding field domains. For our running example with `NUM_Node = 3`, assume that the `Node` class domain is ordered as [$\mathtt{N}_0$,$\mathtt{N}_1$,$\mathtt{N}_2$], and the field domains for `root`, `left`, and `right` are ordered as [`null`,$\mathtt{N}_0$,$\mathtt{N}_1$,$\mathtt{N}_2$].[3] The domain of the `size` field has a single element, 3. According to this ordering, the candidate vectors $[1, 0, 2, 3, 0, 0, 0, 0]$ and

[3]Each field domain order has to preserve the respective class domain orders.

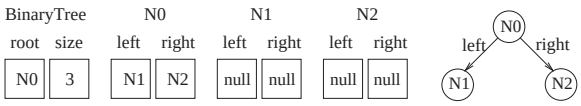

Figure 11: Candidate input that is a valid `BinaryTree`.

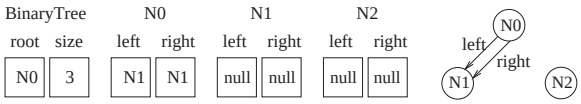

Figure 12: Candidate input that is not a valid `BinaryTree`.

$[1, 0, 2, 2, 0, 0, 0, 0]$ correspond to candidate inputs in figures 11 and 12, respectively.

The search starts with the candidate vector set to all zeros. For each candidate, Korat sets fields in the objects according to the values in the vector. Korat then invokes `repOk` to check the validity of the current candidate. During the execution of `repOk`, Korat monitors the fields that `repOk` accesses. Specifically, Korat builds a *field-ordering*: a list of the field identifiers ordered by the first time `repOk` accesses the corresponding field. Consider the invocation of `repOk` on the candidate shown in Figure 12. In this case, `repOk` accesses only the fields [root,N_0.left,N_0.right] (in that order) before returning `false`. Hence, the field-ordering that Korat builds is `[0,2,3]`.

After `repOk` returns, Korat generates the next candidate vector backtracking on the fields accessed by `repOk`. Korat first increments the domain index for the field that is last in the field-ordering. If the domain index exceeds the domain size, Korat resets that index to zero, and increments the domain index of the previous field in the field-ordering, and so on. (The next section presents how Korat generates only nonisomorphic candidates by resetting a domain index for a field to zero even when the index does not exceed the size of the field domain.)

Continuing with our example, the next candidate takes the next value for N_0.right, which is N_2 by the above order, whereas the other fields do not change. This prunes from the search all 2^8 candidate vectors of the form `[1,-,2,2,-,-,-,-]` that have the (partial) valuation: root=N_0, N_0.left=N_1, N_0.right=N_1. This pruning does not rule out any valid data structure because `repOk` did not read the other fields, and it would have returned `false` irrespective of the values of those fields.

Continuing further with our example, the next candidate is the valid tree shown in Figure 11. For this input, `repOk` returns `true` and the field-ordering built by Korat is `[0,2,3,4,5,6,7,1]`. Note that the first three fields in the field-ordering are the same as before. This is because the `repOk` method accesses fields in a deterministic order and because the values of the first two fields in the field-ordering were not changed when the current candidate was constructed from the previous candidate.

Our algorithm assumes deterministic executions of predicate methods and all the methods that the predicates transitively invoke. In particular, our algorithm assumes that the order of field accesses is solely determined by the candidate input and not by any external input. Similarly, our algorithm assumes that the result of the predicate method is solely determined by the candidate input.

When `repOk` returns `true`, Korat outputs all (nonisomorphic) candidates that have the same values for the accessed fields as the current candidate. (Note that `repOk` may not access all reachable fields before returning `true`.) The search then backtracks to the next candidate. Recall that Korat orders the values in the class and field domains. Additionally, each execution of `repOk` on a candidate imposes an order on the fields in the field-ordering. Together, these orders induce a lexicographic order on the candidates. The search algorithm described here generates inputs in the lexicographical order.

In practice, our search algorithm prunes large portions of the search space, and thus enables Korat to explore very large state spaces. The efficiency of the pruning depends on the `repOk` method. An ill-written `repOk`, for example, might always read the entire input before returning, thereby forcing Korat to explore almost every candidate. However, our experience indicates that naturally written `repOk` methods, which return `false` as soon as the first invariant violation is detected, induce very effective pruning.

3.4 Nonisomorphism

To further optimize the search, Korat avoids generating multiple candidates that are isomorphic to one another. Our optimization is based on the following definition of isomorphism.

Definition: Let $O_1, \ldots, O_n$ be some sets of objects from n classes. Let $O = O_1 \cup \ldots \cup O_n$, and suppose that candidates consist only of objects from O. (Pointer fields of objects in O can either be `null`, or point to other objects in O.) Let P be the set of `null` and all values of primitive types (such as `int`) that the fields of objects in O can contain. Further, let $r \in O$ be a special root object, and let O_C be the set of all objects reachable from r in C. Two candidates, C and C', are *isomorphic* iff there is a permutation π on O, mapping objects from O_i to objects from O_i for all $1 \leq i \leq n$, such that $\forall o, o' \in O_C,\ \forall f \in fields(o),\ \forall p \in P$:

$o.f$==o' in C iff $\pi(o).f$==$\pi(o')$ in C' and
$o.f$==p in C iff $\pi(o).f$==p in C'.

The operator == is Java's comparison by object identity. Note that isomorphism is defined with respect to a root object. Two candidates are defined to be isomorphic if the parts of their object graphs reachable from the root object are isomorphic. In case of `repOk`, the root object is the `this` object that is passed as an implicit argument to `repOk`.

Isomorphism between candidates partitions the state space into *isomorphism partitions*. Recall the lexicographic ordering induced by the ordering on the values in the field domains and the field-ordering built by `repOk` executions. For each isomorphism partition, Korat generates only the lexicographically smallest candidate in that partition.

Conceptually, Korat avoids generating multiple candidates from the same isomorphism partition as follows. For each field in the field-ordering, Korat uses the field domain index to compute the corresponding current class domain and class domain index. For instance, in the example ordering used above for `finBinaryTree(3)`, field domain index `1` for `root` corresponds to the class domain `Node` and class domain index `0`. Further, for each field f in the

```
class SomeClass {
  boolean somePredicate(X x, Y y) {...}
  ...
}
```

Figure 13: Predicate method with multiple arguments

```
class SomeClass_somePredicate {
  SomeClass This;
  X x;
  Y y;
  boolean repOk() {
    return This.somePredicate(x, y);
  }
}
```

Figure 14: Equivalent `repOk` method

field-ordering, Korat finds m_f: the maximum domain index of fields in the field-ordering before f that have the same class domain as f. For all fields f that have no preceding field in the field-ordering with the same class domain as f, Korat sets $m_f = -1$. Then, during backtracking on the field-ordering, Korat checks if incrementing the field domain index for a field f exceeds $m_f + 1$. If it does, Korat resets that index to zero and continues backtracking on the previous field in the field-ordering. The actual Korat implementation uses caching to speed up the computation of m_f.

For example, Korat for `finBinaryTree(3)` generates only the five trees shown in Figure 3. Each tree is a representative from an isomorphism partition that has six distinct trees, one for each of 3! permutations of nodes.

3.5 Instrumentation

To monitor `repOk`'s executions, Korat instruments all classes whose objects appear in finitizations by doing a source to source translation. For each of the classes, Korat adds a special constructor. For each field of those classes, Korat adds an identifier field and special `get` and `set` methods. In the code for `repOk` and all the methods that `repOk` transitively invokes, Korat replaces each field access with an invocation of the corresponding `get` or `set` method. Arrays are similarly instrumented, essentially treating each array element as a field.

To monitor the field accesses and build a field-ordering, Korat uses an approach similar to the *observer* pattern [10]. Korat uses the special constructors to initialize all objects in a finitization with an observer. The search algorithm initializes each of the identifier fields to a unique index into the candidate vector. Special `get` and `set` methods first notify the observer of the field access using the field's identifier and then perform the field access (return the field's value or assign to the field).

3.6 Predicates with multiple arguments

The discussion so far described how Korat generates inputs that satisfy a `repOk` method. This section describes how Korat generalizes this technique to generate inputs that satisfy any Java predicate, including predicates that take multiple arguments. Figure 13 shows a Java predicate that takes two arguments. In order to generate inputs for this predicate, Korat generates an equivalent `repOk` method shown in Figure 14. Korat then generates inputs to the `repOk` method using the technique described earlier.

4. TESTING METHODS

The previous section focused on automatic test case generation from a Java predicate and a finitization description. This section

```
class BinaryTree_remove {
    BinaryTree This;   // the implicit "this" parameter
    BinaryTree.Node n; // the Node parameter
    public boolean repOk() {
        return This.repOk() && This.has(n);
    }
}
```

Figure 15: Class representing `BinaryTree.remove`

```
public static Finitization
        finBinaryTree_remove(int NUM_Node) {
    Finitization f =
        new Finitization(BinaryTree_remove.class);
    Finitization g = BinaryTree.finBinaryTree(NUM_Node);
    f.includeFinitization(g);
    f.set("This", g.getObjects(BinaryTree.class));
    f.set("n", /***/);
    return f;
}
```

Figure 16: Finitization skeleton for `BinaryTree_remove`

presents how Korat builds on this technique to check correctness of methods. Korat uses specification-based testing: to test a method, Korat first generates test inputs from the method's precondition, then invokes the method on each of those inputs, and finally checks the correctness of the output using the method's postcondition.

The current Korat implementation uses the Java Modeling Language (JML) [20] for specifications. Programmers can use JML annotations to express method preconditions and postconditions, as well as class invariants; these annotations use JML keywords `requires`, `ensures`, and `invariant`, respectively. Each annotation contains a boolean expression; JML uses Java syntax and semantics for expressions, and contains some extensions such as quantifiers.

JML specifications can express several *normal* and *exceptional behaviors* for a method. Each behavior has a precondition and a postcondition: if the method is invoked with the precondition (and class invariant) being satisfied, the behavior requires that the method terminate with the postcondition (and class invariant) being satisfied. Additionally, normal behaviors require that the method return without an exception, whereas exceptional behaviors require that the method return with an exception. Korat generates inputs for all method behaviors using the *complete* method precondition that is a conjunction of: 1) the class invariant and 2) a disjunction of the preconditions for all behaviors. In the text that follows, we refer to complete precondition simply as precondition.

4.1 Generating test cases

Valid test cases for a method must satisfy its precondition. To generate valid test cases, Korat creates a class that represents method's inputs. This class has one field for each parameter of the method (including the implicit `this` parameter) and a `repOk` predicate that uses the precondition to check the validity of method's inputs. Given a finitization, Korat then generates all inputs for which this `repOk` returns `true`; each of these inputs is a valid input to the original method.

We illustrate generation of test cases using the `remove` method for `BinaryTree` from Section 2. For this method, each input consists of a pair of `BinaryTree this` and a `Node n`. The complete precondition is `repOk() && has(n)`. Figure 15 shows the class that Korat creates for the method's inputs. For this class, Korat also creates the finitization skeleton that reuses the finitization for `BinaryTree`, as shown in Figure 16.

To create finitization for `BinaryTree_remove`, the programmer can modify the skeleton, e.g., replacing `/***/` with `g.get("root")` or `g.getObjects(BinaryTree.Node.class)` to set the domain for parameter `n` to the domain for the field `"root"` or to the set of nodes from the finitization `g`, respectively. Given a value (n) for `NUM_Node`, Korat then generates all valid test cases, each of which is a pair of a tree (with n nodes) and a node from that tree.

4.1.1 Dependent and independent parameters

For the `remove` method, the precondition makes the parameters `This` and `n` explicitly dependent. When the parameters are independent, programmers can instruct Korat to generating all test cases by separately generating all possibilities for each parameter and creating all valid test cases as the Cartesian product of these possibilities. We next compare Korat with several straightforward approaches for generating all valid (nonisomorphic) test cases.

A straightforward approach for generating all valid test cases is to use the Cartesian product even for dependent parameters. Consider a method `m`, with n parameters and precondition $\mathtt{m}_{pre}$. Suppose that a set of possibilities S_i, $1 \leq i \leq n$, is given for each of the parameters. All valid test cases from $S_1 \times \ldots \times S_n$ can be then generated by creating *all* n-tuples from the product, followed by filtering each of them through $\mathtt{m}_{pre}$. (This approach is used in the JML+JUnit testing framework [5] that combines JML and JUnit [2].) Note that this approach requires manually constructing possibilities for all parameters, some of which can be complex data structures.

Korat, on the other hand, constructs data structures from a simple description of the fields in the structures. Further, in terms of Korat's search of `repOk`'s state space, the presented approach would correspond to the search that tries every candidate input. Korat improves on this approach by: 1) pruning the search based on the accessed fields and 2) generating only one representative from each isomorphism partition.

4.2 Checking correctness

To check a method, Korat first generates all valid inputs for the method using the process explained above. Korat then invokes the method on each of the inputs and checks each output with a *test oracle*. To check partial correctness of a method, a simple test oracle could just invoke `repOk` in the *post-state* (i.e., the state immediately after the method's invocation) to check if the method preserves its class invariant. If the result is `false`, the method under test is incorrect, and the input provides a concrete counterexample. Programmers could also manually develop more elaborate test oracles. Programmers can also check for properties that relate the post-state with the *pre-state* (i.e., the state just before the method's invocation).

The current Korat implementation uses the JML tool-set to automatically generate test oracles from method postconditions, as in the JML+JUnit framework [5]. The JML tool-set translates JML postconditions into runtime Java assertions. If an execution of a method violates such an assertion, an exception is thrown to indicate a violated postcondition. Test oracle catches these exceptions and reports correctness violations. These exceptions are different from the exceptions that the method specification allows. Korat therefore uses JML to check both normal and exceptional behavior of methods. More details of the JML tool-set and translation can be found in [20].

Korat also uses JML+JUnit to combine JML test oracles with JUnit [2], a popular framework for unit testing of Java modules. JUnit automates test execution and error reporting, but requires programmers to provide test inputs and test oracles. JML+JUnit, thus, automates both test execution and correctness checking. However, JML+JUnit requires programmers to provide sets of possibilities for all method parameters: it generates all valid inputs by generating the Cartesian product of possibilities and filtering the tuples using preconditions. Korat additionally automates generation of test cases, thus automating the entire testing process. Table 1 summarizes the comparison of these testing frameworks.

	Testing framework		
testing activity	JUnit	JML+JUnit	Korat
generating test cases	M	M	A
generating test oracle	M	A	A
running tests	A	A	A

Table 1: Comparison of several testing frameworks for Java. Each testing activity is either manual (M) or automated (A).

5. EXPERIMENTAL RESULTS

This section presents the performance results of our current Korat implementation. We have used Java to implement the search for valid nonisomorphic `repOk` inputs. For automatic instrumentation of `repOk` (and transitively invoked methods), we have modified the sources for the Sun's `javac` compiler. We have also modified `javac` to automatically generate finitization skeletons. For checking method correctness, we have slightly modified the JML tool-set, building on the existing JML+JUnit framework [5].

This section first presents Korat's performance for test case generation. We then compare these results with the test generation that uses Alloy Analyzer [15]. We next present Korat's performance for checking method correctness.

All experiments were performed on a Linux machine with a Pentium III 800 MHz processor using Sun's Java 2 SDK1.3.1 JVM.

5.1 Benchmarks

Table 2 lists the benchmarks for which we show Korat's performance. `BinaryTree` and `HeapArray` are presented in Section 2. (`HeapArrays` are similar to array-based stacks and queues, as well as `java.util.Vectors`.)

`LinkedList` is the implementation of linked lists in the Java Collections Framework, a part of the standard Java libraries. This implementation uses doubly-linked, circular lists that have the `header` node as a sentinel node. Each list also has a `size` field. (The methods that linked lists provide allow them to be used as stacks and queues.)

`TreeMap` implements the `Map` interface using red-black trees [7]. This implementation uses binary trees with `parent` fields. Each node (implemented with inner class `Entry`) also has a `key` and a `value`. (Setting all `value` fields to `null` corresponds to `java.util.TreeSet`.)

`HashSet` implements the `Set` interface, backed by a hash table [7]. This implementation builds collision lists for buckets with the same hash code. The `loadFactor` parameter determines when to increase the size of the hash table and rehash the elements.

benchmark	package	finitization parameters
BinaryTree	korat.examples	NUM_Node
HeapArray	korat.examples	MAX_size, MAX_length, MAX_elem
LinkedList	java.util	MIN_size, MAX_size, NUM_Entry, NUM_Object
TreeMap	java.util	MIN_size, NUM_Entry, MAX_key, MAX_value
HashSet	java.util	MAX_capacity, MAX_count, MAX_hash, loadFactor
AVTree	ins.namespace	NUM_AVPair, MAX_child, NUM_String

Table 2: Benchmarks and finitization parameters. Each benchmark is named after the class for which data structures are generated; the structures also contain objects from other classes.

AVTree implements the *intentional name* trees that describe properties of services in the Intentional Naming System (INS) [1], an architecture for service location in dynamic networks. Each node in an intentional name has an attribute, a value, and a set of children nodes. INS uses attributes and values to classify services based on their properties. The names of these properties are implemented with arbitrary Strings, except that "*" is a wildcard that matches all other values. The finitization bounds the number of AVPair objects that implement nodes, the number of children for each node, and the total number of Strings (including the wildcard).

5.2 Korat's test case generation

Table 3 presents the results for generating valid structures with our Korat implementation. For each benchmark, all finitization parameters are set to the same (size) value.[4] For a range of size values, we tabulate the time that Korat takes to generate all valid structures, the number of structures generated, the number of candidate structures checked by repOk, and the size of the state space.

Even for very large state spaces, Korat can effectively generate all structures, because the search pruning allows Korat to explore only a tiny fraction of the state space. The ratios of the number of candidate structures and the sizes of state space show that the key to effective pruning is backtracking based on fields accessed during repOk's executions. Without backtracking, and even with isomorphism optimization, Korat would generate infeasibly many candidates. Isomorphism optimization further reduces the number of candidates, but it mainly reduces the number of valid structures.

For BinaryTree, LinkedList, TreeMap, and HashSet[5], the numbers of nonisomorphic structures appear in the Sloane's On-Line Encyclopedia of Integer Sequences [31]. For all these benchmarks, Korat generates the expected numbers.

5.2.1 Comparison with Alloy Analyzer

We next compare the performance of Korat's test case generation with that of the Alloy Analyzer (AA) [15], an automatic tool for analyzing Alloy *models*. Alloy [16] is a first-order, declarative language based on relations. Alloy is suitable for modeling structural properties of software. Alloy models of several data structures can

[4]For HashSet, the loadFactor parameter is set to 0.75.

	11	926.71	277387	39075006	2^{215}
AVTree	5	62.05	598358	1330628	2^{50}

Table 3: Korat's performance on several benchmarks. All finitization parameters are set to the size value. Time is the elapsed real time in seconds for the entire generation. State size is rounded to the nearest smaller exponent of two.

be found in [23]. These models specify class invariants in Alloy, which corresponds to repOk methods in Korat, and also declare field types, which corresponds to setting field domains in Korat finitizations.

Given a model of a data structure and a *scope*—a bound on the number of atoms in the universe of discourse—AA can generate all (nonisomorphic) *instances* of the model. An instance valuates the relations in the model such that all constraints of the model are satisfied. Setting the scope in Alloy corresponds to setting the finitization parameters in Korat.

AA translates the input Alloy model into a boolean formula and uses an off-the-shelf SAT solver to find a satisfying assignment to the formula. Each such assignment is translated back to an instance of the input model. AA adds symmetry-breaking predicates [30] to the boolean formula so that different satisfying assignments to the formula represent (mostly) nonisomorphic instances of the input model.

Table 4 summarizes the performance comparison. Since AA cannot handle arbitrary arithmetic, we do not generate HashSets with AA. For all other benchmarks, we compare the total number of structures/instances and the time to generate them for a range of parameter values. We also compare the time to generate only one structure/instance by instructing Korat and AA to stop after generating the first structure/instance.

Time presented is the total elapsed real time (in seconds) that each experiment took from the beginning to the end, including start-up.[6] Start-up time for Korat is approximately 0.5 sec. (That is why in some cases it seems that generating all structures is faster than gen-

[6]We include start-up time, because AA does not provide generation time only for generating all instances. We eliminate the effect of cold start by executing each test twice and taking the smaller time.

Table 4: Performance comparison. For each benchmark, performances of Korat and AA are compared for a range of finitization values. For values larger than presented, AA does not complete its generation within 1 hour. Korat's performance for larger values is given in Table 3.

erating one structure or that generating all structures for a larger input is faster than generating all structures for a smaller input.) Start-up time for AA is somewhat higher, approximately 2 sec, as AA needs to translate the model and to start a SAT solver. AA uses precompiled binaries for SAT solvers.

In all cases, Korat outperforms AA; Korat is not only faster for smaller inputs, but it also completes generation for larger inputs than AA. There are several reasons that could account for this difference. Since AA translates Alloy models into boolean formulas, it could be that the current (implementation of the) translation generates unnecessarily large boolean formulas. Another reason is that often AA generates a much greater number of instances than Korat, which takes a greater amount of time by itself. One way to reduce the number of instances generated by AA is to add more symmetry-breaking predicates. However, this would further increase the size of the boolean formulas, and it is not clear how this trade-off would affect AA's performance.

Our main argument for developing Korat was simple: for Java programmers not familiar with Alloy, it is easier to write a `repOk` method than an Alloy model. (From our experience, for researchers familiar with Alloy, it is sometimes easier to write an Alloy model than a `repOk` method.) Before conducting the above experiments, we expected that Korat would generate structures slower than AA. Our intuition was that Korat depends on the executions of `repOk` to "learn" the invariants of the structures, whereas AA uses a SAT solver that can "inspect" the entire formula (representing invariants) to decide how to search for an assignment. The experimental results show that our assumption was incorrect—Korat generates structures much faster than AA. We are now exploring a translation of Alloy models into Java (or even C) and the use of Korat (or a similar search) to generate instances.

5.3 Checking correctness

Table 3 presents the results for checking methods with Korat. For each benchmark, a representative method is chosen; the results

benchmark	method	max. size	test cases generated	gen. time	test time
BinaryTree	remove	3	15	0.64	0.73
HeapArray	extractMax	6	13139	0.87	1.39
LinkedList	reverse	2	8	0.67	0.76
TreeMap	put	8	19912	136.19	2.70
HashSet	add	7	13106	3.90	1.72
AVTree	lookup	4	27734	4.33	14.63

Table 5: Korat's performance on several methods. All upper-limiting finitization parameters for method inputs are set to the given maximum size. These sizes give complete code coverage. Times are the elapsed real times in seconds for the entire generation of all valid test cases and testing of methods for all those inputs. These times include writing and reading of files with test cases.

are similar for other methods. Methods `remove` and `extractMax` are presented in Section 2. Method `reverse`, from `java.util.Collections`, uses list iterators to reverse the order of list elements; this method is static. Method `put`, from `java.util.TreeMap`, inserts a key-value pair into the map; this method has three parameters (`this`, `key`, and `value`) and invokes several helper methods that rebalance the tree after insertion. Method `add` inserts an element into the set. Method `lookup`, from INS, searches a `database` of intentional names for a given `query` intentional name. The correctness specifications for all methods specify simple containment properties (beside preservation of class invariants).

For each method, the `MIN` finitization parameters are set to zero and the `MAX` and `NUM` parameters to the same size value. Thus, the methods are checked for all valid inputs up to the maximum size, not only for the maximum size. For tabulated sizes, these inputs give complete code coverage: they execute all reachable statements for each of the methods (including methods that they transitively invoke in all classes being tested). The results show that it is practical to use Korat to exhaustively check correctness of intricate methods that manipulate complex data structures.

AA can also be used to check correctness of Java methods by writing method specifications as Alloy models and defining appropriate translations between Alloy instances and Java objects, as demonstrated in the TestEra framework [23]. However, the large number of instances generated by AA makes TestEra less practical to use than Korat. For example, maximum sizes six and eight for `extractMax` and `put` methods, respectively, are the smallest that give complete code coverage. As shown in Table 4, for these sizes, AA cannot in a reasonable time even generate data structures that are parts of the inputs for these methods.

6. RELATED WORK

This section presents work that is related to Korat.

6.1 Specification-based testing

There is a large body of research on specification-based testing. An early paper by Goodenough and Gerhart [12] emphasizes its importance. Many projects automate test case generation from specifications, such as Z specifications [14, 32], UML statecharts [26, 27], or ADL specifications [4, 29]. These specifications typically do not consider linked data structures, and the tools do not generate Java test cases.

The TestEra framework [23] generates Java test cases from Al-

loy [16] specifications of linked data structures. TestEra uses the Alloy Analyzer (AA) [15] to automatically generate method inputs and check correctness of outputs, but it requires programmers to learn a specification language much different than Java. Korat generates inputs directly from Java predicates and uses the Java Modeling Language (JML) [20] for specifications. The experimental results also show that Korat generates test cases faster and for larger scopes than AA.

Cheon and Leavens [5] describe automatic translation of JML specifications into test oracles for JUnit [2]. This framework automates execution and checking of methods. However, the burden of test case generation is still on programmers: they have to provide sets of possibilities for all method parameters. Korat builds on this framework by automating test case generation.

6.2 Static analysis

Several projects aim at developing static analyses for verifying program properties. The Extended Static Checker (ESC) [9] uses a theorem prover to verify partial correctness of classes annotated with JML specifications. ESC has been used to verify absence of such errors as null pointer dereferences, array bounds violations, and division by zero. However, tools like ESC cannot verify properties of complex linked data structures.

There are some recent research projects that attempt to address this issue. The Three-Valued-Logic Analyzer (TVLA) [21, 28] is the first static analysis system to verify that the list structure is preserved in programs that perform list reversals via destructive updating of the input list. TVLA has been used to analyze programs that manipulate doubly linked lists and circular lists, as well as some sorting programs. While TVLA is primarily intraprocedural, Role Analysis [19] supports compositional interprocedural analysis and verifies similar properties.

The pointer assertion logic engine (PALE) [25] can verify a large class of data structures, namely all those that can be expressed as graph types [18]. Graph types consist of data structures that can be represented by a spanning tree backbone, with possibly additional pointers that do not add extra information. Graph types include data structures like doubly linked lists, trees with parent pointers, and threaded trees.

While static analysis of program properties is a promising approach for ensuring program correctness in the long run, the current static analysis techniques can only verify limited program properties. For example, none of the above techniques can verify correctness of implementations of balanced trees, such as red-black trees. Testing, on the other hand, is very general and can verify stronger program properties, but for inputs bounded by a given size.

Jackson and Vaziri propose an approach [17] for analyzing methods that manipulate linked data structures. Their approach is to first build an Alloy model of bounded initial segments of computation sequences and then check the model exhaustively with AA. This approach provides static analysis, but it is unsound with respect to both the size of input and the length of computation. Korat not only checks the entire computation, but also handles larger inputs and more complex data structures than those in [17]. Further, Korat does not require Alloy, but JML specifications, and more importantly, unlike [17], Korat does not require specifications for all (helper) methods.

6.3 Software model checking

There has been a lot of recent interest in applying model checking to software. JavaPathFinder [33] and VeriSoft [11] operate directly on a Java, respectively C, program and systematically explore its state to check correctness. Other projects, such as Bandera [6] and JCAT [8], translate Java programs into the input language of existing model checkers like SPIN [13] and SMV [24]. They handle a significant portion of Java, including dynamic allocation, object references, exceptions, inheritance, and threads. They also provide automated support for reducing program's state space through program slicing and data abstraction.

However, most of the work on applying model checking to software has focused on checking event sequences and not linked data structures. Where data structures have been considered, the purpose has been to reduce the state space to be explored and not to check the data structures themselves. Korat, on the other hand, checks correctness of methods that manipulate linked data structures.

7. CONCLUSIONS

This paper presented Korat, a novel framework for automated testing of Java programs. Given a formal specification for a method, Korat uses the method precondition to automatically generate all nonisomorphic test cases bounded by a given size. Korat then executes the method on each of the generated test cases, and uses the method postcondition as a test oracle to check the correctness of each output.

To generate test cases for a method, Korat constructs a Java predicate (i.e., a method that returns a boolean) from the method's precondition. The heart of Korat is a technique for automatic test case generation: given a predicate and a finitization for its inputs, Korat generates all nonisomorphic inputs for which the predicate returns `true`. Korat exhaustively explores the input space of the predicate, but does so efficiently by: 1) monitoring the predicate's executions to prune large portions of the search space and 2) generating only nonisomorphic inputs.

The current Korat implementation uses the Java Modeling Language (JML) for specifications, i.e., class invariants and method preconditions and postconditions. Good programming practice suggests that implementations of abstract data types should already provide methods for checking class invariants—Korat then generates test cases almost for free.

This paper illustrated the use of Korat for testing several data structures, including some from the Java Collections Framework. The experimental results show that it is feasible to generate test cases from Java predicates, even when the search space for inputs is very large. This paper also compared Korat with the Alloy Analyzer, which can be used to generate test cases from declarative predicates. Contrary to our initial expectation, the experiments show that Korat generates test cases much faster than the Alloy Analyzer. The results for checking correctness indicate that it is practical to generate inputs to achieve complete code coverage, even for intricate methods that manipulate complex data structures.
